The effect of different production factors, of which cultivar choice, planting date, planting density, nitrogen fertilization and irrigation are the most important, are reflected in the yield and the malt quality of the crop. The research programs running in the irrigation areas since 1991 are, therefore aimed at identifying the most suitable cultivar with the optimum date and planting density and a nitrogen fertilization application level that will ensure an economical, optimum yield and grain conforming to quality specifications.

From the results obtained from the research program, as well as experience from some commercial plantings in this area in the past, the following recommendations can serve as guidelines for the production of malting barley.

Plant Breeders' Rights (Act 15 of 1976)

The act renders legal protection to the breeders and owners of cultivars. The awarding of rights stipulates that cultivars must be new, distinguishable, uniform and stable, and protection is granted for a period of 20 years. The rights of the owner/ breeder entail that no party may multiply propagating material (seed), process it for planting, sell it, import it, export it or keep it in stock without the necessary authorization or license of the holders of the rights. The act makes provision for the court to grant compensation of R10 000.00 to the holder of Plant Breeder's Rights in cases of breaching of rights.

Seed certification and Table 8, as described in the Plant Improvement Act

The main aim of certification of seed is to maintain cultivars. Seed laws and regulations prescribe the minimum physical requirements, while certification of seed strives to achieve high standards of genetic purity and other quality requirements. Seed certification is a voluntary action that is administered by SANSOR on behalf of the Minister of Agriculture. However, if a cultivar is listed in Table 8, it is subject to compulsory certification. Hereby cultivar purity as well as good seed quality is guaranteed, and renders protection and peace of mind to the buyer (farmer), as well as an improved control system for acting on complaints and claims. The costs involved are surely a minimal price to pay for the peace of mind of both the buyer and seller of certified seed.

Soil Preparation

Soil preparation for the production of barley is the same as for wheat. It must, however, be emphasized that a weed free, fine and very even seedbed is prepared. An uneven seedbed causes uneven development of the crop and in the end also uneven ripening and quality.

Cultivars

The barley cultivars Overture and Genie are at this point in time the only recommended cultivars for commercial production of malting barley under irrigation. The ratio of production between these two cultivars is revised on an annual basis.

The malting characteristics of these cultivars differ and for this reason the mixing of these cultivars must be prohibited at all costs. It is thus imperative that the different cultivars are transported, handled and stored separately.

Seed of both cultivars will be available at the local co-operative and only at the depots as communicated prior to the planting season. These cultivars are only allowed to be delivered at the depots as stipulated in the contract or as communicated beforehand. The seed will be treated with a fungicide as well as an insecticide. This is for the prevention of powdery mildew during the development stages (approximately 10 weeks) of the seedlings and also to prevent covered smut and loose smut, while the insecticide will protect the seed against insect damage for a limited period before it is planted.

Agronomic characteristics

Cultivar choice is economically a very important decision the producer has to make, as it is one of the easiest ways to achieve higher and more stable income with the least risk. Factors that determine cultivar choice are thus fundamental to this decision. Only the most important factors are discussed briefly and for this reason Table 1, which characterizes cultivars in terms of agronomic and quality characteristics, is included.

Growth period

Growth period refers to the average number of days that it takes from emergence to physiological maturity. For this reason cultivars must be planted that are adapted to the climatic conditions, such as growing season, rainfall pattern and temperature of the area.

Straw strength

Straw strength is the ability of a cultivar to remain standing (no lodging) under extreme conditions and is largely determined by straw length and thickness. The lodging of barley often results in considerable yield and grain quality losses, whichcan largely be attributed to the resulting decrease in kernel plumpness. It is largely a problem where critical yield potential conditions have been exceeded, but bad irrigation practices with a strong wind and excessive nitrogen fertilisation and/or seeding density can also play a role.

Peduncle strength

This characteristic refers to the strength of the straw between the flag leaf and the head/ear, and thus to the susceptibility of the cultivar to wind damage (Table 1). The greatest risk of the latter is just prior to harvesting.

Kernel plumpness

The percentage plump kernels largely determine the grade of the grain. This characteristic is strongly cultivar related (Table 1). Under conditions where soil water deficits, water logging and heat stress occur during the grain filling period or where lodging occurs, considerable losses could occur with the downgrading of the crop due to a low kernel plumpness percentage.

Table 1. Agronomic and quality characteristics of barley cultivars

Cultivars	Growth period	Straw length	Straw strength	Peduncle strength	Kernel Plumpness (%)
Genie	M	M	G	M	G
Overture	M	M	G	M	G

Growth period:	*ME = Medium Early*	*M = Medium*
Straw length:	*M = Medium*	
Straw strength:	*G = Good*	*M = Medium*
Peduncle strength:	*G = Good*	
Kernel Plumpness (%)	*G = Good*	

Planting practices

The planting equipment used for the planting of wheat is also suitable for the planting of barley. It is very important that barley is not planted too deep, because this can be detrimental to emergence of the seedlings and also tillering.

The optimum planting date for the different irrigation areas are as follows:

Region	May	June				July		
	4	1	2	3	4	1	2	3
Vaalharts/Taung								
Rietrivier/Douglas								
Luckhoff/Hopetown								
Barkley West								
Northern Irrigation Areas								

Northern Irrigation Areas: Brits, Atlanta, Beestekraal, Koedoeskop, Thabazimbi and Skuinsdrift)

These are only optimum planting dates and do not mean that in certain micro-climates in the mentioned areas, a later or an earlier planting date will not be successful.

The planting density can vary from 60 kg/ha to 9 0 kg/ha depending on the status of the seedbed, the planting date, irrigation method and the planter used. The average recommended planting density is 70 kg/ha, if the seed have 100% germination capacity and a thousand kernel mass of approximately 40 grams. Aim to establish 130 to 140 plants/m² at harvesting. Due to this reason, 60 to 80 kg seed per hectare ought to be sufficient under center pivot conditions where seedbed preparation is optimum, it is important to note that seedbed preparation plays a vital role where lower planting densities are used. It is important to note that seedbed preparation plays a critical role where lower planting densities is used. Under flood irrigation, conditions the planting density should be adjusted upwards (10%). The producer must be aware of the fact that the thousand kernel mass and the germination capacity of the seed can vary from year to year and that he must adjust his seeding density accordingly.

The following table indicates the planting density in kg/ha at the different 1000 kernel masses of the seed in order to realize the desired number of plants/m² at harvesting, with an expected survival of 80%.

Planting density in kg/ha													80		% Germination
1000 Kernel Weight (g) of Seed	Target number of plants/m² at harvesting															
	100	110	120	130	140	150	160	170	180	190	200	210	220	230	240	250

FERTILISATION

Soil acidity requirements

The management of an effective fertilisation program entails soil analyses just prior to the season. As is the case with all crops, a fertilisation program can only be successful if the crop's minimum acidity requirements are met. For barley this has been established at a pH of 5.5 (KCI medium) and the target for lime application to the soil should, therefore, be to create a pH of 5.5 to 6.0. The pH of the soil can rather be higher than 6.0 than lower than 5.5. Yield losses could be severe at lower pH values, but could also occur if the pH is injudiciously raised by more than one pH unit. Unnecessary increases in pH could lead to zinc and manganese deficiencies, something to which barley is very sensitive.

Phosphorus

It is generally accepted that the phosphorus requirement of barley is higher than that of wheat, and that soil analyses are essential for estimating the fertilisation requirement. The objective should be to reach 30 mg/kg citric acid soluble phosphorus, or 20 mg/kg Bray 1 soluble phosphorus in the soil. To achieve this, 4 kg P/ha can be applied for each 1 mg/kg that the analyses is below 30 mg/kg (citric acid), or 6 kg P/ha for each 1 mg/kg that the analysis is below 20 mg/kg (Bray 1). For analyses higher than the above, 6 kg/ha should be applied per ton yield target.

Potassium

Potassium deficiencies are possible in the lighter textured soils in the irrigation areas and where deficiencies do occur, the following guidelines apply:

Table 11. Potassium fertilisation according to soil analysis

Citric acid soluble or ammonium acetate soluble Potassium (mg/kg)	Potassium fertiliser (kg K/ha)
20 - 30	40 - 30
30 - 50	30 - 15
50 - 70	15 - 0
> 70	0

As a rule of thumb an additional 7 kg/ha should be applied per ton yield target.

Experience has shown that a split application of potassium (with planting, 4-6 weeks after emergence and at flag leaf) can decrease the risk of lodging.

Nitrogen

Nitrogen fertilisation can be applied at different growth stages during the development of the barley plant. Under dry land conditions, rainfall is regarded as the most important factor for determining the nitrogen requirements of barley. Under irrigation this is, however, not such a decisive factor and the production system and soil type play a more important role. The first nitrogen is applied just prior to or during the planting process. Top dressing of nitrogen is, according to trial results, beneficial to higher yields and more so for overhead irrigation than flood irrigation. Split applications of nitrogen fertiliser are also more beneficial on lighter sandy soils than on heavier clay soils.

With the increase in yield over the last couple of years, mainly due to genetic improvement, improved production practices and optimum irrigation scheduling, it appears that a total average nitrogen application of 170 kg/ha, depending on the soil texture and rotation system seems to be sufficient for optimum yield and quality.

On a cotton rotation system, and where many maize harvest rests are present just prior to planting, the initial nitrogen application rate can be higher (approximately 20 N/ha more), depending on the soil texture and must be applied as a split application to overcome the nitrogen negative period. On very sandy soils, where leaching of nitrogen is a major problem, an additional 20 kg N/ha is recommended. Although it is not recommended to plant barley directly after lucerne, this practice is widely used. It is important to note that under this condition, N fertilisation needs to be decreased to 120 – 130 kg/ha and preferably all applied within 2 weeks after emergence. Split application of nitrogen fertilisation is more important under overhead irrigation (specifically center pivot) and sandy soils than under flood irrigation and heavy clay soils. A split of 60% of the total nitrogen with planting, another 20% at 4-6 weeks after emergence and the last 20% between flag leaf and 100% heading seems to give the best results. Experience in the practice has shown that barley tends to dislike a small application of nitrogen with planting, followed by the bulk of the nitrogen in a couple of topdressings. The yield potential of barley is mainly determined during the first six weeks after emergence, up to the appearance of the first node. Limestone ammonium nitrate (LAN) appeared to be the best source of nitrogen for topdressing and where nitrogen topdressing is applied through the irrigation system, an ammonium nitrate based fertiliser is recommended. It is also recommended that some part of the nitrogen that is applied at planting, is ammonium nitrate based. Additional nitrogen topdressing after exceptionally heavy rains could be economically beneficial as late as the soft dough stage. On the sandy, high potential soils of the Douglas area, additional topdressing of 20 kg of nitrogen per hectare can be considered.

POST SEEDING PRACTICES

Weed control

Together with fertilisation, the control of weeds can be seen as most important. Barley is very sensitive to competition of weeds and even more so in the early developmental stages of the plants. Early control measures will, therefore, enhance the yield potential of barley and must preferably be done as soon as possible after most weeds have germinated and infestation is high enough to justify control measures. The same guidelines as for weed control in wheat apply for barley. Weeds must be correctly identified (broadleaf and grass weeds), because different herbicides are used for the control of broadleaf and grass weeds. The only herbicides for the control of grass weeds in barley are Hoelon/Ravenger, Axial and Grasp. Under no circumstances must **wheat** herbicides like Topic and Puma be sprayed on barley. The correct amount of herbicide, as recommended on the label, must be applied, because too high dosages can be detrimental to the barley plant and too low dosages will be ineffective. Only herbicides registered specifically on barley, according to the label, are allowed to be used.

Insect control

Barley is a natural host plant for the well-known Russian wheat aphid and some other plant aphids. For early infestation by aphids, an insecticide can be applied with the herbicide. For a late infestation an insecticide has to be applied on its own. The same guidelines apply as for wheat. Barley is, as wheat, susceptible to bollworm damage and the same guidelines for bollworm control apply as for wheat.

During the 2010 season, the false armyworm caused huge damage to plantings, especially in the Vaalharts area. It was, however noticed throughout the entire production area and producers must be on the lookout for this insect. In Australia this is a sporadic plague and not necessary a year on year phenomenon. The Small Grain Institute is currently hard at work to determine a control strategy for this plague. Although no insecticide is specifically registered for the control of false armyworm, the general feeling is that insecticides used for the control of bollworm can also be successful for the control of false armyworm. The Small Grain Institute also undertook to put out pheromone traps to monitor moth flights of the false armyworm. By doing this agriculturalists can notify producers in advance of a possible infestation.

Growth regulation

Although the current cultivars are more resistant to lodging than the older generation cultivars, it is also prone to lodging under very high potential conditions and more so under overhead systems. This problem can be minimized if the crop is not over-irrigated during the early stages of plant development. If the producer is of the opinion that his barley is too lush during the early growth stages and feel that lodging may become a problem, he can stress his crop by applying less water for the period 8 to 12 weeks after emergence. At this specific stage, water stress will have the least negative effect on yield.

Lower planting densities (<140 plants/m²) can also play a significant role in the decrease of lodging given that the seedbed preparation is optimal. Higher seeding densities (>140 plants/m²) leads to longer plants with weaker straw, which is caused by excessive competition for air and light.

Lodging can also be limited by applying a growth regulatorand during the 2018 season, a growth regulator for the use on malting barley was registered for the first time in South Africa. Syngenta Moddus® is currently the only plant growth regulator registered for the use on barley to prevent lodging. It is important to follow the label for dosage and timing of application.

If not applying Moddus® the only way to minimize lodging is to not:

- apply too much nitrogen fertiliser,
- use a too high planting rate,
- over irrigate during the early growing stages of the crop,
- apply too heavy irrigation during the ripening stage of the barley and
- apply irrigation when strong winds prevail.

Fungal control

Fungal diseases do not seem to be a problem in barley under the dry and hot conditions in the irrigation areas. If any diseases do appear on the barley, a representative of ABInBev must be informed immediately for the necessary recommendations.

Fungal contamination of the barley grain in this area is, however, common. Some of these fungi can produce toxic substances (DON) that can be detrimental to humans and livestock. It is thus essential that the crop must be harvested as soon as it is ready, in order to minimize the risk of ripe barley being exposed to rain during harvesting.

Irrigation

Irrigation scheduling must be according to evaporation and needs, as per growth stage. This information is available from your ABInBev representative. It is, however very important that irrigation is not stopped too early and the last irrigation must be applied when the total plant is almost discolored. This is to ensure an even ripening and to produce grain with a high percentage kernel plumpness and acceptable nitrogen content. As mentioned, skilful irrigation practices can minimize lodging and optimize yield and quality (refer to section under growth regulation).

HARVESTING

In the traditional barley producing area, barley is swathed and windrowed before it is threshed. This is mainly done to reduce the risk of damage by strong winds. Barley ears bend downwards when they mature and are prone to be blown off by strong winds and this can cause huge yield losses. The producers in the irrigation areas, however, are not equipped for this practice. That is why it is crucial that the barley must be harvested as soon as it reaches a moisture content of 13% in order to minimize the risk of ripe barley being exposed to possible damage by wind and hail for prolonged periods. Barley can be harvested with the same equipment as wheat with minor adjustments to the drum speed, concave setting and wind. Since the contracts are for the supply of malting barley, it is essential that skinning of the grain be avoided during harvesting. Skinning impairs germination and introduces problems during malting. Thus the combine harvester operation should not be as aggressive as for wheat and care should be taken to avoid an excessively fast drum speed and/or an excessively tight concave setting.

The barley must be harvested in bulk (except where other arrangements have been made) and delivered at the depot as stipulated on the contract or as communicated during the growing season, where it will be sampled, classified and graded. The producer then gets paid according to quantity and quality. Producers will get paid for quality on a sliding scale system as stipulated in the contract.

QUALITY

As from the 2018 season the sliding scale and the consequent payment for quality of barley was adjusted. A variable quality premium will be paid for a kernel nitrogen content of between 1.61% and 1.90% as well as for screenings of 2.4% and lower. It is important that producers must verify these changes with their nearest ABInBev agriculturalist, grain dealer or member of the Barley Industry Committee.

Maltsters require barley that malts homogenous and modifies quickly, requires no or little cleaning and that will deliver malt of an acceptable and consistent quality to brewers. For this reason maltsters set certain quality standards for malting barley to ensure that the end product is produced in the most economical way possible

Nine characteristics, viz. cultivar purity, germination, nitrogen content, kernel plumpness, screenings, foreign matter, mechanical damage, fungal infestation and moisture content are of critical importance in grading and are discussed briefly.

Germination/cultivar purity

Malting barley differs from most cereals as it has to grow again during processing. Germination refers to the percentage barley kernels that are viable within a specified time. It is the most important characteristic of malting barley and must be higher than 98% after the breaking of the dormancy period. Different cultivars have different dormancy periods (rest periods) and therefore, it is important that cultivars are not mixed, but stored separately.

The viability or germination energy of barley can be affected by rain prior to harvesting. If barley is subjected to rain when ripe, biochemical processes in the kernel are initiated that precede germination. The result is uneven or poor germination of the barley during the malting process and produces a poor end product.

Nitrogen content

Barley with extensively high (>2.00) or low nitrogen content (<1.50%) cannot produce malt of the required quality for brewing purposes and will be downgraded to feed grade. The price for barley is based on a base price onto which a premium is added for certain nitrogen levels in the grain (1.61% - 1.90%)

Nitrogen content of barley is a characteristic that is genetically, as well as environmentally, influenced. Certain cultivars produce lower nitrogen content despite higher nitrogen fertilisation. Such a characteristic of a cultivar would be beneficial as it is not only high nitrogen fertilisation that increases the nitrogen levels in the grain, but also uncontrollable factors such as drought and heat stress during the grain filling period and the nitrogen supply capacity of the soil. The producer must at all times also consider the nitrogen supply capability of his soils. Soil tillage and the preceding crop are some of the important factors to keep in mind.

Kernel plumpness

Kernel plumpness is important for homogeneous malting. Thin kernels absorb water faster than plump kernels. Thin kernels also have a relatively higher percentage husk, which gives beer an astringent taste. Therefore, uniform plumpness will result in better malting quality. Barley qualify as malting barley when the kernel plumpness is from 70% upwards, as measured with a 2.5mm sieve. As in the case of nitrogen content, the cut-off point must be confirmed with the grain handlers.

It is also important to note that plump kernels produce malt with a higher extract, which is an important aspect in the brewing process. A low kernel plumpness percentage is the result of unfavorable conditions during the grain filling period, as late ears ripen too fast or if the initial yield potential exceeds the capacity of the environment at the grain-filling stage. Certain cultivars however, also tend to constantly have a lower kernel plumpness and for this reason breeders specifically select for lines with high kernel plumpness. The kernel plumpness of all the present barley cultivars can be described as good to very good.

Screening, foreign matter and mechanical damage

Screenings is material that is so small that it falls through a 2.2 mm sieve and needs to be less than 5%. This material generally consists of shriveled kernels, broken kernels, small weed seeds, glumae, awns, dead insects and dust.
Thin kernels can be ascribed to factors noted, while broken kernels, glumae, awns and dust generally reflect on harvester adjustments. For this reason it is imperative that the producer adjusts his harvester correctly to ensure good quality.

Dead weevils in the screenings are usually an indication of a possible infestation and this would require further investigation. The presence of weevils can lead to downgrading of the crop due to the live insects on the one hand or the presence of insect damaged kernels on the other hand.

The cut-off point for foreign matter is 2%, a feed grade price is applicable for barley with a foreign matter content >2%.

Mechanical damage by harvesters decreases the percentage of usable barley kernels. When embryos are damaged or, husk over the embryo is removed, the kernels cause problems in the malting process. A too high percentage of endosperm exposed kernels results in several processing problems in the malting process (fungal growth, foam in steep tanks etc.).

Fungal infection

Malting barley infected with fungi is not considered fit for human consumption and is downgraded to under grade. Some fungi produce mycotoxins (DON) when under stress. Fungal infection usually takes place when grain, that is ready for harvesting, is subjected to continual moist conditions or when barley with too high moisture content is harvested and stored on the farm under unfavorable conditions. Barley cultivars have no genetic resistance to these fungi that occur on the grain.

Moisture Content

Malting barley that is delivered and stored with too high a moisture content can lead to fungal development and also a decrease in germination capacity. Due to this reason no malting barley with a moisture content of higher than 13% will be accepted.

BARLEY PASSPORT

As from the 2005 season a system was implemented by which the producer is obliged to submit a passport before he can deliver his first load of barley. This barley passport entails a schedule that has to be completed by the producer in co-operation with his chemical agent and must clearly stipulate which chemicals have been applied on the barley as well as when it was applied, how it was applied and the dosage used. It is therefore of the utmost importance that the passport has to be fully completed and handed in at the delivery depot before any grain will be accepted.

Lastly it is also important to note that no grain will be accepted that was treated with an unregistered chemical, unregistered dosage or unregistered application method. For more information, the local ABInBev representative can be contacted Germination/cultivar purity

SUMMARY

The production of barley of good quality with an optimum yield, starts and ends at the producer and the following points are of the utmost importance:

- pH of the soil must be higher than 5.5 (KCl) and preferably between 5.5 and 6.0 (KCl).
- Phosphate status of the soil must be sufficient (30 mg/kg citric acid soluble P) or of such a nature that it can be rectified with a one-time application.
- Planting date is of the utmost importance and barley must be planted during the optimum recommended planting date for the specific area.
- Planting density may vary between 60 and 90 kg/ha, depending on the status

sa barley breeding institute

of the seedbed, irrigation method and the planting equipment that is used.Germination capacity and thousand kernel mass must also be taken into account.

- A total average nitrogen fertilisation of 170 kg/ha (depending on the soil type and rotation system) is optimal in terms of yield and quality. Directly after Lucerne the N fertilisation needs to be decreased to 125 kg/ha and preferably all needs to be applied with planting.
- Split application of nitrogen fertilisation is more important under overhead irrigation (specifically center pivot) than under flood irrigation and on lighter sandy soils. A split of 60% of the total nitrogen with planting, another 20% at 4-6 weeks after emergence and the last 20% between flag leaf and 100% heading seems to give the best results.
- Optimum planting, fertilisation and irrigation practices should be applied to minimize the problem of lodging. Syngenta Moddus plant growth regulator is now registered for the use on barley in order to reduce lodging.
- Irrigation scheduling must be according to evaporation and needs as per growth stage. Irrigation must not be withdrawn too early and the last irrigation must be applied when the crop is almost completely discolored.
- Harvesting must commence as soon as the crop is ready for threshing (13% moisture content) in order to minimize possible damage by wind and hail, as well as weather damage of grain (fungal contamination).
- The combine harvester operation should not be as aggressive as for wheat in order to avoid skinning.
- Only use registered chemicals, at the registered dosage and according to the registered application method.

Barley can compete very well with wheat in irrigation areas with regard to quality and yield, if above-mentioned criteria are adhered to and climatic conditions do not differ significantly from the long-term average.
